## Supporting Information

**ABSTRACT:** Supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts were investigated for propylene metathesis as a function of surface rhenia loading and extensively characterized with in situ UV–vis, Raman, IR, XANES/EXAFS, and isotopic  $^{18}\text{O}$ – $^{16}\text{O}$  exchange studies. The experimental studies were complemented with DFT calculations using realistic models of the alumina surface. The surface  $\text{ReO}_x$  sites were found to be isolated surface dioxo  $(\text{O}=\text{O})_2\text{ReO}_2$  species, which represent the most stable surface rhenia structures on alumina as shown by DFT. Two distinct surface  $\text{ReO}_4$  species, however, were found to be present and only slightly differ in their bridging  $\text{Re}–\text{O}–\text{Al}$  bond lengths brought about by anchoring at different sites of the  $\text{Al}_2\text{O}_3$  support. The deformed surface  $\text{ReO}_4\text{–I}$  species preferentially anchor at more basic  $\mu_1\text{Al}_{\text{IV}}$  and  $\mu_1\text{Al}_{\text{VI}}$  sites and are difficult to activate for propylene metathesis. The surface  $\text{ReO}_4\text{–II}$  species are formed at more acidic  $\mu_2\text{Al}_{\text{VI}}$  and  $\mu_3\text{Al}_{\text{VI}}$  sites and are the catalytic active sites for propylene metathesis. The surface  $\text{ReO}_4\text{–II}$  sites were readily activated by propylene while the deformed surface  $\text{ReO}_4\text{–I}$  sites were almost not affected by propylene, with only a few sites being activated. The steady-state propylene metathesis reaction rates are much higher for the surface  $\text{ReO}_4\text{–II}$  sites than the deformed surface  $\text{ReO}_4\text{–I}$  sites. The formation of the less reactive deformed surface  $\text{ReO}_4\text{–I}$  species could be blocked by occupation of the  $\mu_1\text{Al}_{\text{IV}}$  sites with sacrificial surface  $\text{TaO}_x$  species that resulted in catalysts exclusively containing the more active surface  $\text{ReO}_4\text{–II}$  sites on alumina. This is the first study to demonstrate that the surface  $\text{ReO}_4\text{–II}$  sites are the precursors for the catalytic active sites for propylene metathesis by supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  catalysts and to molecularly design olefin metathesis catalysts that exclusively contain isolated surface  $\text{ReO}_4\text{–II}$  sites.

## 1. INTRODUCTION

Supported rhenium oxide catalysts find wide applications in numerous chemical processes.<sup>1–3</sup> For olefin metathesis, rhenium oxide supported on  $\text{Al}_2\text{O}_3$  stands out because it is active and selective at low temperatures.<sup>1</sup> The industrial importance of olefin metathesis reactions, especially to meet the current global shortage of propylene by on purpose propylene production,<sup>4</sup> has stimulated numerous fundamental studies about the nature of the  $\text{Re}^{7+}$  oxide catalyst precursor supported on alumina. In particular, multiple in situ characterization studies (Raman, IR, and XAS) and DFT calculations have confirmed that the surface rhenium oxide species are present as isolated sites on alumina.<sup>5–13</sup> The most commonly assigned molecular structure for the dehydrated  $\text{Re}^{7+}$  oxide on  $\text{Al}_2\text{O}_3$  has been the trioxo  $(\text{O}=\text{O})_3\text{Re}–\text{O}–\text{Al}$  site ( $C_{3v}$  symmetry).<sup>5–12</sup> The nature of the surface  $\text{Re}^{7+}$  oxide species on alumina has recently come into question because of

reported contradictory conclusions.<sup>12,13</sup> Bare et al. concluded that isolated trioxo  $(\text{O}=\text{O})_3\text{Re}–\text{O}–\text{Al}$  species are present for calcined supported rhenia/alumina catalysts<sup>12</sup> mainly from EXAFS analysis. In contrast, Scott et al. postulated isolated penta-coordinated dioxo  $(\text{O}=\text{O})_2\text{Re}(-\text{O}-\text{Al})_3$  from XANES/EXAFS measurements and DFT calculations employing cluster models.<sup>13</sup> The precise coordination of the isolated surface  $\text{Re}^{7+}$  oxide species on alumina is of great importance to understand the remarkable low-temperature olefin metathesis activity of this catalyst system. Indeed, it was shown for alumina supported Mo-oxo-carbene reactive intermediate complexes that the strain induced by multiple interactions with the support can strongly enhance the catalytic properties.<sup>14</sup> The

Revised: December 25, 2014

structural analysis of surface  $\text{Re}^{7+}$  oxide species on alumina is further complicated because two slightly different dehydrated surface rhenia species have been observed by in situ Raman spectroscopy as a function of rhenia loading.<sup>5,6</sup> It is, thus, of paramount importance to settle the previously mentioned  $\text{Re}^{7+}$  oxide structural debate and understand the catalytic structure–reactivity relationships for the supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalyst system for olefin metathesis as a function of rhenia loading and anchoring sites on the alumina support.

In the present study, comprehensive in situ Raman, IR, UV–vis, and XANES/EXAFS experimental studies and DFT calculations are undertaken to determine the nature of surface  $\text{ReO}_x$  species on the  $\text{Al}_2\text{O}_3$  support and their structure–reactivity relationships for olefin metathesis. The domain size or nuclearity of the surface  $\text{ReO}_x$  species are examined with in situ UV–vis spectroscopy. The average coordination of the surface  $\text{ReO}_x$  species is accessed with in situ XANES and the radial distribution of the atoms surrounding Re with in situ EXAFS. The molecular structure(s) and anchoring site(s) of the surface  $\text{ReO}_x$  species on alumina are probed with in situ Raman and IR spectroscopy, respectively, and isotopic  $^{18}\text{O}/^{16}\text{O}$  exchange Raman measurements. A number of possible DFT surface models are compared for multiple surface  $\text{Re}^{7+}$  oxide sites (trioxo, dioxo, and mono-oxo coordinated rhenium oxide centers) on the (100) and (110) surfaces of  $\gamma$ -alumina. The alumina surfaces are described by a periodic slab.<sup>15,16</sup> The experimental in situ isotopic  $^{18}\text{O}/^{16}\text{O}$  Raman band splitting patterns for supported  $\text{ReO}_x$  on alumina are compared with those obtained from theoretical calculations for the possible  $\text{ReO}_x$  species on the most dominant (110) alumina surface. Structure–reactivity relationships are developed for olefin metathesis of the supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts by comparing the relationships between the initial surface  $\text{ReO}_x$  structures and their olefin metathesis reactivity.

## 2. RESULTS

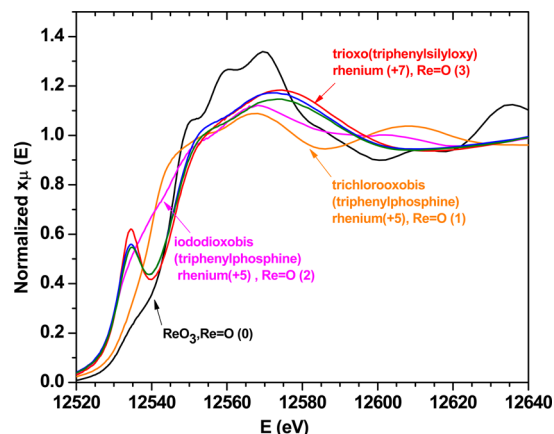

**2.1. In Situ UV–vis Spectroscopy.** The in situ UV–vis edge energy ( $E_g$ ) values for the dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts are presented in Figure 1 and exhibit a constant  $E_g$  value of  $\sim 4.2$  eV for all surface rhenia coverage (0.14–2.2 Re atoms/ $\text{nm}^2$ ). The high UV–vis  $E_g$  value reflects the presence of only isolated surface rhenia species on alumina because the  $E_g$  values are comparable to those for the isolated  $\text{ReO}_4$ -containing

**Figure 1.** In situ UV–vis  $E_g$  values for dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  (Engelhard batch, E) catalysts as a function of rhenia surface coverage.

$\text{NaReO}_4$  (3.9 eV),  $\text{KReO}_4$  (4.0 eV), and  $\text{NH}_4\text{ReO}_4$  (4.0 eV) reference compounds and significantly higher than the  $E_g$  value for the oligomeric  $\text{Re}_2\text{O}_7$  reference compound (2.8 eV) (see Figure S1). The absence of surface oligomeric and crystalline  $\text{Re}_2\text{O}_7$  nanoparticles is a consequence of the volatility of dimeric and polymeric  $\text{Re}_2\text{O}_7$  species, which assures that only isolated surface rhenia species are present on alumina.<sup>5,6</sup>

**2.2. In Situ XANES and EXAFS Spectroscopies.** The in situ XANES spectra of the supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts under dehydrated conditions are shown in Figure 2.

**Figure 2.** In situ  $\text{Re L}_1$  XANES spectra for the dehydrated supported 3% (blue) and 15.6% (olive)  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts. The XANES spectra of the reference compounds, trioxo(triphenylsilyloxy) rhenium(+7) (red), iododioxobis (triphenylphosphine) rhenium(+5) (magenta), trichlorooxobis (triphenylphosphine) rhenium(+5) (orange), and  $\text{ReO}_3$  rhenium(+6) oxide (black) are taken under ambient conditions.

The coordination of the  $\text{ReO}_x$  site is reflected by the  $\text{Re L}_1$  XANES pre-edge feature. For metal oxides with  $\text{MO}_6$  coordination,  $\text{O}_h$  and inversion symmetry, the  $s$ – $d$  transitions are dipole forbidden and, thus, there is no K or  $\text{L}_1$  pre-edge.<sup>17,18</sup> Bulk  $\text{ReO}_3$  possesses  $\text{ReO}_6$  coordination (Figure S4), and the slight  $\text{L}_1$  pre-edge is related to its minor distortion. Strong deviations from the  $\text{MO}_6$   $\text{O}_h$  symmetry result in a sharp pre-edge feature in the  $\text{Re L}_1$  edge XANES reflecting the absence of inversion symmetry.<sup>17</sup> The trioxo(triphenylsilyloxy) rhenium (+7) reference compound consists of  $\text{ReO}_4$  coordinated isolated  $(\text{O}=\text{O})_3\text{ReO-Si}(\text{phenyl})_3$  units containing  $\text{C}_{3v}$  symmetry (Figure S4) and exhibits a sharp  $\text{Re L}_1$  XANES pre-edge because of the absence of inversion symmetry. The other rhenia reference compounds do not exhibit a strong  $\text{Re L}_1$  XANES pre-edge. The in situ  $\text{Re L}_1$  XANES spectra for the dehydrated supported 3% and 15.6%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts possess a strong pre-edge feature approaching that of the trioxo(triphenylsilyloxy)  $\text{Re}^{7+}$  reference compound with  $\text{C}_{3v}$  symmetry. The slightly lower intensity of the pre-edge for the catalysts suggests that the  $\text{ReO}_x$  symmetry is slightly lower than  $\text{C}_{3v}$ , which may also be affected by some adsorption of residual moisture. The almost same XANES pre-edge intensity for both dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts also indicates that the surface  $\text{ReO}_x$  coordination does not change much with rhenia loading on the  $\text{Al}_2\text{O}_3$  support.

The  $k^2$  weighted  $\text{Re L}_1$ -edge EXAFS data of the corresponding samples are presented in Figure 3. The  $(\text{O}=\text{O})_3\text{ReO-Si}(\text{phenyl})_3$  reference compound with isolated rhenia sites exhibits a strong peak at  $\sim 1.2$  Å from the terminal

**Figure 3.** Magnitudes of Fourier-transformed, not-phase-corrected,  $k^2$ -weighted  $\text{Re } L_1$ -edge EXAFS spectra in the  $R$  space for the dehydrated supported 3% $\text{ReO}_x/\text{Al}_2\text{O}_3$  (blue) and 15.6% $\text{ReO}_x/\text{Al}_2\text{O}_3$  (olive) catalysts with the reference trioxo ( $\text{O}=\text{O}$ ) $_3\text{ReO-Si-(phenyl)}_3$  (red), iododioxobis (triphenylphosphine) rhenium(+5) (magenta), trichlorooxobis (triphenylphosphine) rhenium(+5) (orange) and crystalline bulk  $\text{ReO}_3$  (black) compounds.

$\text{Re}=\text{O}$  bonds. The absence of strong peaks at high  $R$  distance is consistent with the isolated nature of the ( $\text{O}=\text{O}$ ) $_3\text{ReO-Si-(phenyl)}_3$  reference compound. With the decrease in the number of  $\text{Re}=\text{O}$  bonds (3 in trioxo ( $\text{O}=\text{O}$ ) $_3\text{ReO-Si-(phenyl)}_3$ , 2 in iododioxobis (triphenylphosphine) rhenium, and 1 in trichlorooxobis (triphenylphosphine) rhenium), the intensity of the EXAFS peak at  $\sim 1.2$  Å decreases. The crystalline bulk  $\text{ReO}_3$  reference compound contains its  $\text{Re-O}$  peak at  $\sim 1.5$  Å reflecting the longer metal–oxygen bond length in  $\text{ReO}_3$  and absence of  $\text{Re}=\text{O}$  bonds in this structure. The bulk crystalline  $\text{ReO}_3$  reference also possesses strong peaks in the 2–5 Å range, originating from the  $\text{Re-Re}$  single scattering path and several multiple scattering paths of this solid compound. The dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts have a pronounced peak at  $\sim 1.2$  Å, similar to the location of the peak corresponding to  $\text{Re}=\text{O}$  bonds in the references. For both catalysts, the intensity of the peak at  $\sim 1.2$  Å is almost the same and is between the intensities of the corresponding peaks in the standard compounds with 3 and 2  $\text{Re}=\text{O}$  bonds. This type of change is consistent with the change of the number of  $\text{Re}=\text{O}$  pairs in the catalysts, and agrees well with the changes in the pre-edge peak of the corresponding XANES spectra. These two independent observations suggest that the catalysts possess mainly terminal  $\text{Re}=\text{O}$  bonds, and their coordination numbers can be estimated between 2 and 3 with symmetry less than  $\text{C}_{3v}$ . The absence of high  $R$  peaks in the spectra of catalysts reflects the isolated nature of the surface rhenia species on alumina, which is consistent with the above in situ UV–vis findings. Quantitative analysis yields the effective  $\text{Re}=\text{O}$  bond lengths of 1.72–1.75 Å for both species (Supporting Information (SI)). This is in agreement with the  $\text{Re}=\text{O}$  bond length values published in the recent literature,<sup>12,13</sup> but the actual number of  $\text{Re}=\text{O}$  bonds cannot be reliably obtained from EXAFS analysis because those contributions to EXAFS also correlate strongly with the single  $\text{Re-O}$  bonds at longer distances (e.g., 1.76 Å, as discussed later in the DFT section). The description of fitting models compared for the quantitative data analysis is presented in the SI.

**2.3. In Situ Raman Spectroscopy.** **2.3.1. Supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  Catalysts under Dehydrated Conditions.** The in

situ Raman spectra of the dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts are presented in Figure 4. The supported 3%  $\text{ReO}_x/$

**Figure 4.** In situ Raman spectra (442 nm) of dehydrated supported 3% and 9.4%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  (Harshaw batch, H) catalysts at 100 °C. The inset shows the 900–1100  $\text{cm}^{-1}$  region.

$\text{Al}_2\text{O}_3$  catalyst, with a low surface rhenia coverage of 0.44  $\text{Re}/\text{nm}^2$ , exhibits Raman bands at  $\sim 1002$   $\nu_s(\text{Re}=\text{O})$  (s),  $\sim 970$   $\nu_{\text{as}}(\text{Re}=\text{O})$  (w),  $\sim 879$   $\nu_s(\text{Re-O-Al})$  (m) and  $\sim 340$   $\delta(\text{O-Re-O})$  (m)  $\text{cm}^{-1}$  for the surface rhenia species (labeled  $\text{ReO}_x\text{-I}$ ). Supported catalysts with 5%  $\text{ReO}_4$  ( $\geq 0.74$   $\text{Re}/\text{nm}^2$ ) and higher rhenia loading, as shown for 9.4%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  in Figure 4, possess a new  $\nu_s(\text{Re}=\text{O})$  (s) band at  $\sim 1012$   $\text{cm}^{-1}$  from a second surface rhenia species (labeled  $\text{ReO}_x\text{-II}$ ) because each structure can only give rise to one symmetric stretch according to vibrational spectroscopy selection rules.<sup>19</sup> The surface  $\text{ReO}_x\text{-II}$  species possess vibrations at 1012  $\nu_s(\text{Re}=\text{O})$  (s),  $\sim 976$   $\nu_{\text{as}}(\text{Re}=\text{O})$  (w),  $\sim 890$   $\nu_s(\text{Re-O-Al})$  (m), and  $\sim 340$   $\delta(\text{O-Re-O})$  (m)  $\text{cm}^{-1}$ . The absence of vibrations from bending  $\delta_s(\text{Re-O-Re})$  (m) at  $\sim 150$ – $250$   $\text{cm}^{-1}$ , stretching  $\nu_s(\text{Re-O-Re})$  (w) at  $\sim 400$ – $600$   $\text{cm}^{-1}$  and stretching  $\nu_{\text{as}}(\text{Re-O-Re})$  (vw) at  $\sim 600$ – $800$   $\text{cm}^{-1}$  (see SI, Figure S7 for the Raman spectrum of solid  $\text{Re}_2\text{O}_7$ ) is further consistent with the isolated nature of the surface  $\text{ReO}_x$  species on alumina.<sup>5,6</sup>

**2.3.2. Supported  $\text{ReO}_x/\text{TaO}_x/\text{Al}_2\text{O}_3$  under Dehydrated Conditions.** The simultaneous presence of two dehydrated surface  $\text{ReO}_x$  species at high surface rhenia coverage on alumina greatly complicates molecular structural analysis of the surface  $\text{ReO}_x\text{-II}$  site. To resolve this problem, we chose to use a second surface metal oxide that may behave similarly to surface  $\text{ReO}_x\text{-I}$  and does not give rise to strong Raman bands that would interfere with the rhenia vibrations (the motivation for this strategy is given below in section 3.4.2). Surface  $\text{TaO}_x$  was selected as the second metal oxide because previous studies showed that the supported  $\text{TaO}_x/\text{Al}_2\text{O}_3$  system does not give strong Raman bands (as shown in SI, Figure S8 for 15%  $\text{Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$ , which is about half a monolayer of surface  $\text{TaO}_x$  on alumina).<sup>20</sup> The influence of the secondary surface  $\text{TaO}_x$  species on the supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalyst system is also shown in SI, Figure S8, and only the Raman vibrations corresponding to the surface  $\text{ReO}_x\text{-II}$  species on alumina are found at  $\sim 1010$   $\nu_s(\text{Re}=\text{O})$  (s),  $\sim 980$   $\nu_{\text{as}}(\text{Re}=\text{O})$  (w), 890  $\nu_s(\text{Re-O-Al})$  (m) and 345  $\delta(\text{O-Re-O})$  (m)  $\text{cm}^{-1}$ .<sup>5,6</sup> The order of impregnation and calcination of  $\text{TaO}_x$  or  $\text{ReO}_x$  does not affect the final results (compare  $\text{ReTaAl}$  and  $\text{TaReAl}$  spectra in SI, Figure S8) suggesting that surface  $\text{TaO}_x$  is able to

block formation surface  $\text{ReO}_x$ -I species and, thus, increase the number of surface  $\text{ReO}_x$ -II sites. This is the first time that the surface  $\text{ReO}_x$ -II species have been successfully isolated on the alumina support.

**2.3.3. Isotopic  $^{16}\text{O}$ - $^{18}\text{O}$  Exchange of Supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  Catalysts.** Time-resolved in situ Raman spectroscopy isotopic  $^{18}\text{O}$ - $^{16}\text{O}$  exchange studies were undertaken with  $\text{H}_2^{18}\text{O}$  to assist in the discrimination between surface trioxo ( $(\text{O}=\text{O})_3\text{ReO}_x$ , dioxo ( $(\text{O}=\text{O})_2\text{ReO}_x$ , and mono-oxo  $\text{O}=\text{ReO}_x$  species on alumina. During isotopic oxygen exchange, (i) trioxo species are expected to split into four Raman bands ( $(=^{16}\text{O})_3$ ,  $(=^{16}\text{O})_2(=^{18}\text{O})$ ,  $(=^{16}\text{O})(=^{18}\text{O})_2$  and  $(=^{18}\text{O})_3$ ), dioxo species should split into three Raman bands ( $(=^{16}\text{O})_2$ ,  $(=^{16}\text{O})(=^{18}\text{O})$  and  $(=^{18}\text{O})_2$ ), and mono-oxo species will split into two Raman bands ( $(=\text{O}^{16})$  and  $(=\text{O}^{18})$ .

The time-resolved isotopic oxygen exchange Raman spectra for the supported 3%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  (H) catalyst that only possesses the surface  $\text{ReO}_x$ -I species are presented in Figure 5.

**Figure 5.** In situ Raman spectra (442 nm) of 3%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  ( $\text{ReO}_x$ -I) (H) at 200 °C during  $^{18}\text{O}$ - $^{16}\text{O}$  isotope exchange by exposure to  $\text{H}_2^{18}\text{O}$  vapor.

The time-resolved Raman spectra indicate three  $\nu_s(\text{Re}=\text{O})$  vibrations that are only consistent with dioxo surface  $\text{ReO}_x$  species at  $\sim 1000$  ( $^{16}\text{O}=\text{Re}=\text{O}$ ), 992 ( $^{18}\text{O}=\text{Re}=\text{O}$ ) and  $943\text{ cm}^{-1}$  ( $^{18}\text{O}=\text{Re}=\text{O}$ ). The corresponding  $\delta(\text{O}-\text{Re}-\text{O})$  mode shifts from 337 to  $321\text{ cm}^{-1}$  during the isotopic exchange process while the broad  $\nu_s(\text{Re}-\text{O}-\text{Al})$  band at  $880\text{ cm}^{-1}$  and weak  $\nu_{as}(\text{Re}=\text{O})$  band at  $969\text{ cm}^{-1}$  stretching vibrations become too weak to detect.

The time-resolved isotopic oxygen exchange Raman spectra for the supported 10%  $\text{ReO}_x/10\%\text{ Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$  (E) catalyst that only possesses the surface  $\text{ReO}_x$ -II species are presented in Figure 6. The time-resolved Raman spectra indicate three  $\nu_s(\text{Re}=\text{O})$  vibrations that are only consistent with dioxo surface  $\text{ReO}_x$  species at  $\sim 1010$  ( $^{16}\text{O}=\text{Re}=\text{O}$ ), 995 ( $^{18}\text{O}=\text{Re}=\text{O}$ ) and  $950\text{ cm}^{-1}$  ( $^{18}\text{O}=\text{Re}=\text{O}$ ). The corresponding  $\delta(\text{O}-\text{Re}-\text{O})$  mode shifts from 345 to  $327\text{ cm}^{-1}$  during the isotopic exchange, whereas the broad  $\nu_s(\text{Re}-\text{O}-\text{Al})$  band at  $897\text{ cm}^{-1}$  and the very weak  $\nu_{as}(\text{Re}=\text{O})$  band at  $\sim 980\text{ cm}^{-1}$  become too weak to detect with the isotopic oxygen exchange.

**2.4. In Situ IR Spectroscopy under Dehydrated Conditions.** **2.4.1. Overtone Region.** The strong absorption of the IR radiation by the  $\text{Al}_2\text{O}_3$  support prevents observation of the  $\text{Re}=\text{O}$  and  $\text{Re}-\text{O}$  vibrations in the fundamental

**Figure 6.** In situ Raman spectra (442 nm) of supported 9.36%  $\text{ReO}_x/10\%\text{ Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$  ( $\text{ReO}_x$ -II) (E) at 200 °C during  $^{18}\text{O}$ - $^{16}\text{O}$  isotope exchange with  $\text{H}_2^{18}\text{O}$  vapor.

frequency region ( $\sim 1000\text{ cm}^{-1}$  and below). The  $\text{Re}=\text{O}$  vibrations, however, can be observed in the overtone region and the in situ IR spectra of the dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts in the overtone region are shown in SI, Figure S9. The supported 3%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalyst that only contains the surface  $\text{ReO}_x$ -I species gives rise to two broad bands in the overtone region at  $\sim 1996$  (s) and  $\sim 1962$  (s)  $\text{cm}^{-1}$  from the  $\nu_s(\text{Re}=\text{O})$  and  $\nu_{as}(\text{Re}=\text{O})$  vibrations, respectively. At higher surface rhenia coverage, two additional shoulders appear at  $\sim 2020$  (m) and  $\sim 1971$  (m)  $\text{cm}^{-1}$  are also present from the  $\nu_s(\text{Re}=\text{O})$  and  $\nu_{as}(\text{Re}=\text{O})$  vibrations of the surface  $\text{ReO}_x$ -II species, respectively. These observations and assignments are in agreement with prior IR studies of supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts and further support the presence of two distinct surface  $\text{ReO}_x$  species on alumina.<sup>6</sup> The IR bands, however, are very broad and significantly overlap compared to the sharper Raman bands, which makes Raman the preferred method to monitor the surface  $\text{ReO}_x$  species on alumina.

**2.4.2. Surface Hydroxyl (OH) Groups.** **2.4.2.1. Supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  Catalysts under Dehydrated Conditions.** The alumina surface hydroxyls of under dehydrated conditions have been extensively studied in the catalysis literature and at least 5 types of surface hydroxyls are present and their coordination to the different surface alumina sites are given in Table 1.<sup>15,16,21,22</sup>

**Table 1.**  $\text{Al}_2\text{O}_3$  hydroxyl types and band positions ( $\text{cm}^{-1}$ ) reported in the literature

band positions	crystal faces <sup>15,16</sup>	structure of hydroxyl sites (from DFT) <sup>15,16</sup>
3785–3800	(110)	HO- $\mu_1$ -Al <sub>IV</sub>
3760–3780	(100)	HO- $\mu_1$ -Al <sub>VI</sub>
3730–3735	(110)	HO- $\mu_1$ -Al <sub>V</sub>
3690–3710	(110)	HO- $\mu_2$ -Al <sub>V</sub>
3590–3650	(100)	HO- $\mu_3$ -Al <sub>VI</sub>

The in situ IR spectra of the surface hydroxyl region of the dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts as a function of rhenia loading are presented in Figure 7. At low surface  $\text{ReO}_x$  coverage (3%  $\text{ReO}_x/\text{Al}_2\text{O}_3$ ), mainly the  $\mu_1$ -Al<sub>IV</sub>,  $\mu_1$ -Al<sub>VI</sub> and  $\mu_1$ -Al<sub>V</sub> surface hydroxyls at 3787, 3768, and  $3743\text{ cm}^{-1}$ , respectively, are consumed due to anchoring of the surface rhenia species on alumina. Minor amounts of  $\mu_3$ -Al<sub>VI</sub> surface

**Figure 7.** In situ IR spectra of the surface hydroxyl region of dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  (E) catalysts as a function of rhenia loading at 200 °C. The blue color represents  $\text{ReO}_x\text{-I}$ , and the green color represents  $\text{ReO}_x\text{-II}$ .

hydroxyls at  $3670\text{ cm}^{-1}$  also appear to be consumed. At intermediate surface  $\text{ReO}_4$  coverage (9.4%  $\text{ReO}_x/\text{Al}_2\text{O}_3$ ), the consumption of the  $\mu_1\text{-Al}_V$  hydroxyl at  $3728\text{ cm}^{-1}$  becomes significant, the  $3694\text{ cm}^{-1}$   $\mu_2\text{-Al}_V$  hydroxyl are only slightly consumed and there does not appear to be any significant amount of  $\mu_1$  surface hydroxyls ( $3730\text{--}3800\text{ cm}^{-1}$ ) remaining. At the highest surface  $\text{ReO}_x$  coverage (15.6%  $\text{ReO}_x/\text{Al}_2\text{O}_3$ ), almost all of the IR observable alumina surface hydroxyls have been consumed. There is no indication for the formation of  $\text{Re}\text{--OH}$  hydroxyls under the dehydrated conditions. The in situ IR spectra reveal that different alumina surface hydroxyls are employed in anchoring the surface  $\text{ReO}_x$  species on the alumina support and explain why more than one surface  $\text{ReO}_x$  species is present on the alumina support with rhenia coverage.

**2.4.2.1. Supported  $\text{ReO}_x/\text{Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$  Catalysts.** The surface  $\text{TaO}_x$  species anchor at the same basic surface hydroxyl sites consumed by surface  $\text{ReO}_x\text{-I}$  species (see SI, Figure S10). Consequently, the surface rhenia species can only anchor at the surface hydroxyl sites available for forming surface  $\text{ReO}_x\text{-II}$  species.

**2.5. In Situ Raman Spectroscopy during Propylene Metathesis.** In situ Raman spectra were also collected during propylene metathesis (1%  $\text{C}_3\text{H}_6/\text{He}$  at 70 °C), and the spectra for the supported 3% $\text{ReO}_x/\text{Al}_2\text{O}_3$  (H), 9.4% $\text{ReO}_x/\text{Al}_2\text{O}_3$  (H) and 5% $\text{ReO}_x/15\%\text{TaO}_x/\text{Al}_2\text{O}_3$  (E) are presented in panels a, b, and c, respectively, of Figure 8. The surface  $\text{ReO}_x\text{-I}$  species ( $\sim 1003\text{ cm}^{-1}$ ) are minimally perturbed by the reaction environment, only decreasing its Raman intensity by  $\sim 3\text{--}7\%$  up to 120 min as shown in Figure 8a,b. The surface  $\text{ReO}_x\text{-II}$  species ( $\sim 1011\text{ cm}^{-1}$ ), however, clearly undergo preferential interaction with propylene over the surface  $\text{ReO}_x\text{-I}$  species during propylene metathesis, as shown in Figure 8c. The strong interaction of propylene with the surface  $\text{ReO}_x\text{-II}$  sites, formed by addition of 15%  $\text{TaO}_x$  to 5%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  that suppresses formation of surface  $\text{ReO}_x\text{-I}$  sites, is clearly indicated in Figure 8c, as the intensity of the Raman band is almost completely diminished after 120 min of reaction. Recovery of the initial surface  $\text{ReO}_x$  Raman bands after reaction by reoxidation of the catalysts indicates that the decreased Raman intensity during propylene metathesis was not caused by volatilization of surface rhenia from the catalyst.

**Figure 8.** In situ Raman spectra (442 nm) of the (a) 3% $\text{ReO}_x/\text{Al}_2\text{O}_3$  (H), (b) 9.4% $\text{ReO}_x/\text{Al}_2\text{O}_3$  (H), and (c) 5% $\text{ReO}_x/15\%\text{TaO}_x/\text{Al}_2\text{O}_3$  (E) catalysts during propylene metathesis at 70 °C up to 120 min. The catalyst was reoxidized in 10%  $\text{O}_2/\text{Ar}$  at 550 °C after the reaction.

**2.6. Density Functional Theory Calculations.** **2.6.1. Surface  $\text{ReO}_x$  Structures on the  $\text{Al}_2\text{O}_3$  Support.** Comparison of the adsorption energy of a model  $\text{HReO}_4$  compound shows that the  $\text{Al}_2\text{O}_3(110)$  termination has a higher reactivity toward the surface  $\text{ReO}_x$  species compared to the more stable  $\text{Al}_2\text{O}_3(100)$  facet (see SI). This is a general feature for many Lewis base molecules and is related to the presence at the (110) surface of low coordinated  $\text{Al}_{\text{III}}$  and  $\text{Al}_{\text{IV}}$  sites, which present efficient acceptor orbitals of low energy (especially the  $\text{Al}_{\text{III}}$  site), whereas the (100) termination show less reactive  $\text{Al}_{\text{V}}$  surface atoms.<sup>23</sup> Hence occupation of the  $\text{Al}_2\text{O}_3(110)$  surface by the  $\text{ReO}_x$  species is most probable, and the DFT calculations below will be limited to the  $\text{Al}_2\text{O}_3(110)$  facet. An extensive discussion of the DFT calculations of surface  $\text{ReO}_x$  species on the less reactive  $\text{Al}_2\text{O}_3(100)$  surface can be found in SI (Figure

S2). The Al<sub>III</sub> sites result from the truncation at the (110) surface of tetra-coordinated Al atoms that are specific to the  $\gamma$ -alumina structure and are absent in  $\alpha$ -alumina. The calculations here are performed in the limit of low hydroxyl content of the surface, however, at moderate hydration level accessible metastable structures with strong Lewis acid are also seen on the (110) alumina surface.<sup>24</sup>

The supported rhenia structures obtained for the majority (110)  $\gamma$ -alumina surface are shown in Figure 9.

**Figure 9.** DFT optimized structures and relative energies for the surface Re<sup>7+</sup> oxide species supported on (110)  $\gamma$ -alumina. Bond lengths are given in Å.

The optimized rhenia structures obtained for the (110)  $\gamma$ -alumina surface are especially important because this is the most exposed surface on alumina nanoparticles and is also more unsaturated; consequently, it is more reactive than the (100) surface.<sup>15,16</sup> This produces a larger variety of surface rhenium oxide species compared to the (100) plane, and the surface rhenium oxide species are also more strongly bonded to the alumina support. The optimized ReO<sub>x</sub> structures in Figure 9 possess trioxo, dioxo, and mono-oxo rhenium oxide coordination. The predicted Re=O bond lengths for the free Re=O bonds are typically 1.72 Å for the mono-oxo and dioxo structures, and 1.73 Å for the trioxo species 110<sub>10</sub>, again in accordance with the EXAFS results.<sup>12,13</sup> An interaction between

the oxo ligand and surface hydroxyl group causes an elongation of the double bond to 1.75 Å (110<sub>8</sub>). The formally single Re–O bonds involved in Re–O–Al linkages are nonequivalent with their lengths varying over a wide range from 1.76 to 2.01 Å.

The relative energies of the obtained structures sometimes differ dramatically. The trioxo species with the C<sub>3v</sub> symmetry (110<sub>10</sub>) is clearly predicted to be unstable, and other attempts to obtain trioxo Re<sup>7+</sup> structures resulted in dioxo species. The formation of mono-oxo Re<sup>7+</sup> species was also considered (110<sub>3</sub>, 110<sub>5</sub>, and 110<sub>6</sub>) because of the high reactivity of the alumina surface. Each of the rhenium mono-oxo structures is 4-fold bonded to the alumina surface with three bridging Re–O–Al bonds and one additional dative bond from a surface oxygen atom to the rhenium atom. The most stable structures, however, are the surface dioxo species (110<sub>1</sub> and 110<sub>2</sub>). Although they are very close in energies, their geometries are not identical. For the 110<sub>1</sub> structure, the ReO<sub>4</sub> unit is strongly deformed toward a C<sub>2v</sub> symmetry with two additional weak and long Re...O bonds (2.35 Å) forming with surface O atoms. Such interactions, where the Re atom plays the role of a Lewis acid, complete the Re coordination and only form on the Al<sub>2</sub>O<sub>3</sub> (110) surface because they require more basic oxygen atoms. There are two bridging oxygen atoms in this species, connected to one AlO<sub>4</sub> and two AlO<sub>5</sub> aluminum atoms, respectively (here we refer to the final coordination of these Al atoms after interaction with Re). The surface 110<sub>2</sub> species appears as a ReO<sub>4</sub> coordinated unit. The rhenium atom is connected via two oxygen bridges with one AlO<sub>4</sub> and one AlO<sub>5</sub> site. The surface rhenia structures obtained here, stabilized by multiple interactions with the surface, are consistent with earlier computational study on methyltrioxorhenium adsorbed on (110)  $\gamma$ -Al<sub>2</sub>O<sub>3</sub>.<sup>23</sup> A detailed discussion concerning the stability of the surface rhenium species in terms of deformation and interaction energy is included in SI.

The present DFT optimization study with realistic alumina surface models strongly supports the proposal that surface rhenium oxide species on  $\gamma$ -alumina exhibit a dioxo ReO<sub>4</sub> structure and do not reproduce the proposed penta-coordinated dioxo Re species.<sup>13</sup> Because this (110) termination shows two structures with very similar energy, calculations suggest that the supported catalyst may be a mixture of different binding modes of the ReO<sub>4</sub> on  $\gamma$ -alumina, most likely having the surface (110<sub>1</sub>) and (110<sub>2</sub>) structures. It should, however, be noted that species of similar geometry can significantly differ in their stability, depending on their specific location on the surface (for instance, compare 110<sub>1</sub> and 110<sub>9</sub>). Hence, surface stability of the ReO<sub>x</sub> species might be strongly dependent on the detailed geometry of the alumina surface. The presence of defects or of different levels of hydration may also affect the complex geometry and stability.<sup>24</sup> Additional information is, thus, mandatory to confirm the trend proposed by the energy calculations.

#### 2.6.2. Predicted Raman Vibrations from DFT Calculations.

A key link with experiment is established by the calculation of vibrational frequencies. A benchmark study of Re=O frequencies with a well-characterized family of gas phase rhenium oxide compounds (data obtained from literature<sup>25–28</sup>) indicates that for optimum accuracy, a scale factor of 0.9900 needs to be applied (Table 2). Note that the correction with respect to raw calculated data is small. The very good agreement between theoretical and experimental values is another validation of the adopted methodology in this study.

**Table 2. Calculated and Experimental Re=O Stretching Frequencies (cm<sup>-1</sup>) for Reference Rhenium Oxide Reference Compounds, after the Determination of the Optimum Scaling Factor of 0.9900**

<sup>a</sup>A scale factor of 0.9900 is used. <sup>b</sup>ref 25. <sup>c</sup>ref 26. <sup>d</sup>ref 27. <sup>e</sup>ref 28.

The calculated Raman vibrations of each of the supported ReO<sub>x</sub> structures on the alumina surface are presented in [SI Table S1](#). It should be noted that Re=O and Re–O–Al vibrations are often coupled to each other. Furthermore, the vibrations of the mono-oxo, dioxo, and trioxo surface ReO<sub>x</sub> structures overlap, and it is not possible to discriminate between the different structures on the positions of the bands alone. For example, all the surface ReO<sub>x</sub> structures on the Al<sub>2</sub>O<sub>3</sub>(100) surface exhibit their strong  $\nu_s(\text{Re}=\text{O})$  stretch in the narrow region: between 987 and 997 cm<sup>-1</sup> and on the Al<sub>2</sub>O<sub>3</sub>(110) surface mono-oxo 110\_3 and 110\_5 (996 and 992 cm<sup>-1</sup>), dioxo 110\_7 (990 cm<sup>-1</sup>), and trioxo 110\_10 (997 cm<sup>-1</sup>) are too close to be able to distinguish between them.

Isotopic oxygen exchange studies give key additional information in order to discriminate between mono-oxo, dioxo, and trioxo surface ReO<sub>x</sub> species on the most dominant Al<sub>2</sub>O<sub>3</sub>(110) surface as shown experimentally above with Raman spectroscopy. The calculated isotopic <sup>18</sup>O–<sup>16</sup>O shifts in the Re=O stretching frequencies for the most stable dioxo Re species on the (110)  $\gamma$ -alumina surface (110\_1 and 110\_2) are shown in Table 3. Additionally, the theoretical frequencies for the mono-oxo (110\_3) and trioxo (110\_10) Re models after the isotopic exchange are also presented. In the calculations, the <sup>18</sup>O–<sup>16</sup>O substitution has been considered only for the oxo ligands (Re=O bonds) that dominate these vibrations. In the case of the partially substituted dioxo and trioxo species, all possible substitution patterns are taken into account for the determination of the theoretical frequencies. The calculated Re(<sup>18</sup>O)(=<sup>16</sup>O), Re(=<sup>18</sup>O)(=<sup>16</sup>O)<sub>2</sub>, and Re(=<sup>18</sup>O)<sub>2</sub>(=<sup>16</sup>O) frequencies hardly depend on the substitution sequence. In most cases, the Re=O stretching modes are coupled with the Re–O–Al vibrations.

The calculated isotopic shifts for the 110\_1 and 110\_2 dioxo surface ReO<sub>4</sub> species are consistent with the experimental data for the supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts (Table 4), especially for the symmetric Re=O modes. The theoretically predicted frequencies for the fully substituted trioxo Re species (962, 922, and 915 cm<sup>-1</sup> in Table 3) are different from the corresponding experimental values assigned to the species ReO<sub>x</sub>-I and ReO<sub>x</sub>-II (950–942 cm<sup>-1</sup> in Table 4), confirming that surface ReO<sub>x</sub> species are not trioxo. The calculated  $\nu_s(\text{Re}=\text{O})$  (996 cm<sup>-1</sup>) and  $\nu_{\text{as}}(\text{Re}=\text{O})$  (945 cm<sup>-1</sup>) frequencies for the mono-oxo species 110\_3 (Table 4) are close to the observed bands of the symmetric modes for the nonsubstituted (1000 cm<sup>-1</sup>) and fully substituted (943 cm<sup>-1</sup>) species ReO<sub>x</sub>-I, respectively (Table 4). However, in contrast to (110\_1), the mono-oxo ReO<sub>x</sub> species does not match all the observed bands and its existence is not confirmed experimentally. Such mono-oxo species as (110\_3) cannot entirely be excluded as minority species by the DFT

<sup>a</sup>Strongly coupled with  $\nu(\text{Re}-\text{O}-\text{Al})$ . <sup>b</sup> $\nu(\text{O}=\text{Re}-\text{O}-\text{Al})$  coupled with  $\nu(\text{Al}-\text{O}-\text{Re}-\text{O}-\text{Al})$ . <sup>c</sup>It was not possible to isolate and assign this vibration to an individual species.

calculations because their vibrational stretching modes may be screened by the symmetric vibrations of the major dioxo species. Therefore, the combination of total energy calculations and of frequency calculations including isotopic exchange show that the two most energetically favored species on the most dominant 110 planes, 110\_1 and 110\_2, are observed experimentally as surface ReO<sub>4</sub>-I and ReO<sub>4</sub>-II, respectively.

**2.7. Steady-State Propylene Metathesis.** The steady-state catalytic performance of the supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts for propylene metathesis to ethylene and 2-butene is shown in Figure 10. The same trend is also obtained

**Figure 10.** Steady-state catalytic performance for propylene metathesis at 70 °C by supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> (blue squares) and ReO<sub>x</sub>/15% TaO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> (green squares) catalysts that were dehydrated in flowing O<sub>2</sub>/Ar at 500 °C for prior to reaction at 70 °C. The reaction was performed with ReO<sub>x</sub> catalysts supported on Al<sub>2</sub>O<sub>3</sub> (E). The dashed line indicates the *x*-axis shift for ReTaAl catalysts to show the promotion effect of the surface TaO<sub>x</sub> species. The slight offset may be due to experimental error such as volatilization of ReO<sub>x</sub> at higher loading.

independent of the activity normalization (g of catalyst or m<sup>2</sup> because all the catalysts possess similar BET values). For the supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalyst, there is almost no propylene metathesis activity below ~5% ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> (0.74 Re/nm<sup>2</sup>) loading, and the metathesis activity increases continuously only with ReO<sub>x</sub> loading above ~5% ReO<sub>x</sub> (0.74 Re/nm<sup>2</sup>). Comparison of the propylene metathesis activity with the surface ReO<sub>x</sub>-I and ReO<sub>x</sub>-II structures on alumina determined above suggests that the surface ReO<sub>x</sub>-I sites possess minimal activity for metathesis. Although the Ta<sub>2</sub>O<sub>5</sub>/Al<sub>2</sub>O<sub>3</sub> support is not active for propylene metathesis, the addition of surface TaO<sub>x</sub> species significantly promotes the activity of supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalyst by increasing the propylene metathesis at

all surface rhenia coverage on alumina (e.g., by a factor of ~10× for 3% ReO<sub>x</sub> and ~4× for 9.4% ReO<sub>x</sub>). Furthermore, it appears that the surface TaO<sub>x</sub> species only replace the surface ReO<sub>x</sub>-I sites because the ReO<sub>x</sub>/TaO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> activity curve matches the activity of ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> by shifting the curve to higher rhenia loadings as shown by the dashed line in Figure 10. This suggests that the surface TaO<sub>x</sub> sites on alumina do not participate in the propylene metathesis reaction.

### 3. DISCUSSION

**3.1. Molecular Structures and Anchoring Sites of the Surface ReO<sub>x</sub> Species on Al<sub>2</sub>O<sub>3</sub>.** Only isolated surface ReO<sub>x</sub> species are present on the alumina support because dimeric Re<sub>2</sub>O<sub>7</sub> or higher rhenia oligomers are volatile. This is the reason for the volatilization of rhenia from alumina at high surface rhenia coverage.<sup>5,6</sup> The isolated nature of the surface ReO<sub>x</sub> site on alumina is supported by the very high UV–vis *E<sub>g</sub>* values and the absence of observable Re–Re distances in the second coordination sphere at ~3–4 Å in the EXAFS radial distribution of the dehydrated supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts.<sup>12,13</sup> TOF-SIMS analysis of calcined supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts also demonstrated that the surface ReO<sub>x</sub> species are essentially isolated on the alumina support.<sup>29</sup>

The intense Re L<sub>1</sub> XANES pre-edge feature of the supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> catalysts approaches that of the (O=)<sub>3</sub>ReO-Si-(phenyl)<sub>3</sub> reference compound in (see Figure 2), which strongly suggests that the surface ReO<sub>x</sub> sites possess ReO<sub>4</sub> coordinated with only slightly different symmetry than C<sub>3v</sub> from the reference compound. The presence of the two long Re...O bonds (2.35 Å) bonds for the deformed (110\_1) surface ReO<sub>4</sub> structure does not appear to influence its first coordination shell and, thus, its XANES pre-edge features. Structures with other symmetries such ReO<sub>6</sub> or ReO<sub>5</sub> would give rise to very weak or intermediate XANES Re L<sub>1</sub> pre-edges, respectively. The somewhat weaker Re=O peak in the Re L<sub>1</sub> EXAFS of the dehydrated supported ReO<sub>x</sub>/Al<sub>2</sub>O<sub>3</sub> relative to the trioxo (O=)<sub>3</sub>ReO-Si-(phenyl)<sub>3</sub> reference compound suggests less Re=O character and more Re–O character for the surface ReO<sub>4</sub> sites on the Al<sub>2</sub>O<sub>3</sub> support. The isotopic <sup>18</sup>O–<sup>16</sup>O oxygen exchange measurements confirm that the surface ReO<sub>4</sub> sites contain two oxo ligands (O=Re=O) (see Figure 5). This molecular structure is also supported by the DFT calculations indicating that the most stable surface rhenia structures on alumina are dioxo surface ReO<sub>4</sub> species. Moreover, spectroscopy and theory demonstrate that two distinct dioxo species are present. Dioxo surface ReO<sub>4</sub>-I is assigned to the 110\_1 in Figure 9, where, besides the two Re=O bonds, there are also two bridging Re–O–Al bonds and two much longer Re...O–Al bonds to the support, with the latter outside of the first coordination sphere of the surface ReO<sub>4</sub>-I

site. The dioxo surface  $\text{ReO}_4\text{-II}$  is assigned to the slightly less stable DFT-calculated structure 110\_2 in Figure 9 with two oxo bonds ( $\text{O}=\text{Re}=\text{O}$ ) and two longer bridging  $\text{Re}-\text{O}-\text{Al}$  bonds. For the  $\text{Re}=\text{O}$  vibrational stretch frequencies, DFT calculations also predict the observed isotopic shift from  $\sim 1003/976$  to  $\sim 1014/985\text{ cm}^{-1}$  for the surface  $\text{ReO}_4\text{-I}$  and  $\text{ReO}_4\text{-II}$  sites, respectively, on the alumina (110) surface (see Table 4).

The slight structural differences between the surface  $\text{ReO}_4\text{-I}$  and  $\text{ReO}_4\text{-II}$  sites is directly related to the bridging  $\text{Re}-\text{O}-\text{Al}$  bonds (1.83/1.94 Å and 1.79/1.81 Å on the  $\text{Al}_2\text{O}_3$  (110) surface, respectively) and to an angular distortion of the tetrahedral Re center in  $\text{ReO}_4\text{-I}$ , because both rhenia sites have the same  $\text{Re}=\text{O}$  bond lengths of 1.72 Å. The surface  $\text{ReO}_4\text{-I}$  site on alumina (110) is connected to one  $\text{Al}_{\text{IV}}$  site and two  $\text{Al}_{\text{V}}$  sites, in agreement with the observed preferential consumption of basic alumina  $\mu_1$  surface hydroxyls for 1–5%  $\text{ReO}_4/\text{Al}_2\text{O}_3$  in the IR spectra (see Figure 7). The surface  $\text{ReO}_4\text{-I}$  site requires Lewis acid Al sites and additional surface basic O atoms for its stabilization on the alumina (110) surface. In the DFT model (110\_2), the  $\text{ReO}_4$  species is supported by a vacant alumina surface and hence is a metastable case. In the experiment, surface  $\text{ReO}_4\text{-II}$  only appears after a loading of 5% and hence is anchored at  $\mu_2\text{-Al}_{\text{VI}}$  and  $\mu_3\text{-Al}_{\text{VI}}$  sites in agreement with the observed preferential consumption of the corresponding  $\mu_2\text{-Al}_{\text{V}}$  and  $\mu_3\text{-Al}_{\text{VI}}$  surface hydroxyls on alumina (110) for 5–15.6%  $\text{ReO}_4/\text{Al}_2\text{O}_3$  (see Figure 7). The impregnation of  $\text{Ta}_2\text{O}_5$  consumes  $\text{Al}_{\text{IV}}$  and  $\text{Al}_{\text{V}}$  sites, which are involved in anchoring surface  $\text{ReO}_4\text{-I}$  species and, hence, only allows selective formation of surface  $\text{ReO}_x\text{-II}$  at low Re loading (see SI, Figure S10). Regardless of the order of impregnation, the surface  $\text{ReO}_4\text{-II}$  species are always dominant on the  $\text{Al}_2\text{O}_3$  support in the presence of  $\text{Ta}_2\text{O}_5$  due to the higher mobility of surface  $\text{ReO}_x$  species.

As seen above, the most stable surface  $\text{ReO}_x$  sites on  $\text{Al}_2\text{O}_3$  are the surface dioxo ( $\text{O}=\text{O}$ ) $\text{ReO}_2$  sites as predicted by DFT calculations based on the stability of different surface  $\text{ReO}_x$  structures on realistic models of the  $\text{Al}_2\text{O}_3$  surface and confirmed experimentally with in situ XANES and isotopic  $^{18}\text{O}\text{-}^{16}\text{O}$  exchange Raman spectroscopy. The current DFT optimizations do not reproduce the proposed penta-coordinated dioxo ( $\text{O}=\text{O}$ ) $\text{ReO}_3$  species as a stable surface  $\text{ReO}_x$  structure.<sup>13</sup> The most common proposed structure in the literature for surface  $\text{ReO}_x$  sites on alumina has been the trioxo ( $\text{O}=\text{O}$ ) $\text{Re}-\text{O}-\text{Al}$  structure.<sup>5–12</sup> The  $^{18}\text{O}\text{-}^{16}\text{O}$  exchange Raman findings are not consistent with trioxo species and the DFT calculations clearly indicate that the trioxo  $\text{ReO}_4$  structure is not stable on the alumina (110) surface. The formation of mono-oxo  $\text{O}=\text{ReO}_4$  species was also considered (see structures 110\_3, 110\_5, and 110\_6 in Figure 9), but the presence of mono-oxo  $\text{O}=\text{ReO}_4$  species is also not supported by the  $^{18}\text{O}\text{-}^{16}\text{O}$  exchange findings and DFT calculations predict the mono-oxo  $\text{ReO}_x$  structure to be less stable than dioxo on the alumina (110) surface. The two previous structural assignments of surface trioxo ( $\text{O}=\text{O}$ ) $\text{ReO}$  and penta-coordinated dioxo ( $\text{O}=\text{O}$ ) $\text{ReO}_3$  were based on fitting of the EXAFS radial distributions of the oxygen atoms surrounding the  $\text{Re}^{7+}$  site.<sup>12,13</sup> The current EXAFS analysis indicates that it is not possible to determine the exact number of  $\text{Re}=\text{O}$  bonds with EXAFS alone since both the  $\text{Re}=\text{O}$  and  $\text{Re}-\text{O}$  bonds have similar bond lengths that complicates analysis. In addition, EXAFS analysis, which averages over the two surface  $\text{ReO}_4$  sites on  $\text{Al}_2\text{O}_3$ , further complicates molecular structural analysis. Although the surface dioxo ( $\text{O}=\text{O}$ ) $\text{ReO}_2$

structure has previously not been proposed in the literature, the current experimental and theoretical calculations strongly indicate that it is the stable surface rhenia species on dehydrated supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts.

**3.2. Influence of the Propylene Metathesis Reaction Conditions on the Surface  $\text{ReO}_4\text{-I}$  and  $\text{ReO}_4\text{-II}$  Sites on  $\text{Al}_2\text{O}_3$ .** The in situ Raman studies of the supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  catalysts (3%  $\text{ReO}_4/\text{Al}_2\text{O}_3$  with only surface  $\text{ReO}_4\text{-I}$  sites, 15.6%  $\text{ReO}_4/\text{Al}_2\text{O}_3$  with both surface  $\text{ReO}_4\text{-I}$  and surface  $\text{ReO}_4\text{-II}$  sites, and 3%  $\text{ReO}_4/15\%$   $\text{Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$  with only surface  $\text{ReO}_4\text{-II}$  sites) during propylene metathesis clearly demonstrate that the surface  $\text{ReO}_4\text{-I}$  sites are minimally perturbed by propylene and that all the surface  $\text{ReO}_4\text{-II}$  sites readily interact with propylene (see panels a, b, and c, respectively, of Figure 8). The nature of the surface  $\text{ReO}_x\text{-II}$  sites interacting with propylene is the subject of a subsequent study and will not be currently addressed.

The interaction of all the surface  $\text{ReO}_4\text{-II}$  sites on  $\text{Al}_2\text{O}_3$  with propylene is unexpected because the olefin metathesis literature has been under the impression that only a very small number of sites,  $\sim 1\%$   $\text{ReO}_4$ , are active sites for metathesis.<sup>29</sup> This conclusion was reached from olefin metathesis titration studies at ambient temperatures (25–50 °C). The titration measurements were conducted at ambient temperatures after several hours of olefin metathesis and exposing the catalyst to vacuum for several hours to remove residual physically adsorbed olefins from the catalysts before titration with a second olefin. The presence of a significant amount of inactive surface  $\text{ReO}_4\text{-I}$  species on alumina in these studies further contributed to the estimated low apparent number of active sites. The estimated fraction of surface  $\text{ReO}_4\text{-II}$  sites on alumina in prior studies is indicated in Figure 11, revealing that the surface  $\text{ReO}_4\text{-II}$  sites were the minority species and the surface  $\text{ReO}_4\text{-I}$  sites were the majority (but inactive) species for half of the studies.<sup>1,13,30–41</sup>

The current study, however, demonstrates that the number of active surface  $\text{ReO}_4\text{-II}$  sites for olefin metathesis is a variable number that depends on the surface  $\text{ReO}_4$  coverage on alumina

**Figure 11.** Comparison of estimated surface  $\text{ReO}_4\text{-II}$  concentration as a function of Re loading for supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts that have been reported in the literature. The solid line indicates the concentration of surface  $\text{ReO}_4\text{-II}$  species as a function of Re coverage on alumina determined in the present study. The concentration of surface  $\text{ReO}_x\text{-II}$  species for other experimental data is estimated from the solid line generated in the present study. The studies reporting surface rhenia coverage higher than maximum of  $2.2\text{Re}/\text{nm}^2$  did not account for volatility of rhenia above this loading and, thus, can only contain a maximum of  $\sim 2.2\text{Re}/\text{nm}^2$ .

as well as the presence of acidic surface metal oxides that block the formation of the less reactive surface  $\text{ReO}_4\text{-I}$  sites. Furthermore, "titration" with olefin is not a titration process, but actually, it is an activated chemical reaction that strongly depends on temperature. Thus, "titration" of the surface intermediates with olefins at ambient temperatures cannot react away all or even a significant fraction of the surface intermediates. The present investigation is the first direct observation that propylene selectively interacts with surface  $\text{ReO}_4\text{-II}$  sites on  $\text{Al}_2\text{O}_3$  during propylene metathesis. With the assistance of the surface  $\text{TaO}_x$  promoter, it is even possible to design catalysts approaching 100%  $\text{ReO}_4\text{-II}$  that are all interacting with propylene. Such higher concentrations of activated sites for supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  catalysts, as well as other supported metal oxide olefin metathesis catalysts, finally opens the opportunity to characterize the activated surface  $\text{ReO}_4$  sites on alumina.

**3.3. Molecular Structure–Reactivity Relationships of Surface  $\text{ReO}_4\text{-I}$  and  $\text{ReO}_4\text{-II}$  Sites on  $\text{Al}_2\text{O}_3$  for Propylene Metathesis.** The steady-state catalytic studies indicate that the surface  $\text{ReO}_4\text{-II}$  sites are the catalytic active sites for propylene metathesis since the surface  $\text{ReO}_4\text{-I}$  sites do not exhibit significant catalytic activity. The surface  $\text{ReO}_4\text{-I}$  sites may even be inactive and the residual minimal activity may originate from trace amounts of surface  $\text{ReO}_4\text{-II}$  sites. The propylene metathesis steady-state catalytic trend as a function of surface rhenia loading on alumina has been observed in previous kinetic studies,<sup>1,13,42,43</sup> but this is the first time that the surface dioxo  $\text{ReO}_4\text{-II}$  site on alumina has been isolated and identified as the precursor to the catalytic active site for propylene metathesis by supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  catalysts. The major structural differences between surface  $\text{ReO}_4\text{-I}$  and  $\text{ReO}_4\text{-II}$  sites are their anchoring sites on the alumina surface and the resulting (Al–O)–Re–(O–Al) angle. The alumina anchoring sites act as potent multidentate ligands that moderate the activation of the surface  $\text{ReO}_4$  sites for propylene metathesis. The weak interaction of surface  $\text{ReO}_4\text{-I}$  with two additional surface O atoms also certainly decreases its Lewis acidity compared to  $\text{ReO}_4\text{-II}$ .

The addition of surface  $\text{TaO}_x$  sites promotes the supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  catalyst for propylene metathesis by occupying the surface  $\text{Al}_{\text{IV}}$  sites on the alumina support and, consequently, blocks formation of the less active surface  $\text{ReO}_4\text{-I}$  sites. As a result, the surface rhenia sites are forced to occupy the  $\text{Al}_{\text{V}}$  and  $\text{Al}_{\text{VI}}$  sites that result in selective formation of surface  $\text{ReO}_4\text{-II}$  sites. This is further emphasized by shifting the propylene activity curve for the supported  $\text{ReO}_4/\text{TaO}_x/\text{Al}_2\text{O}_3$  catalyst by 4–5%  $\text{ReO}_4$  toward the activity curve for Ta-free supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  catalyst as shown in Figure 10. The overlap of the Ta-promoted and -unpromoted activity curves demonstrates that indeed the surface  $\text{TaO}_x$  sites are occupying the sites normally occupied by surface  $\text{ReO}_4\text{-I}$  and that surface  $\text{TaO}_x$  is not promoting the supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  by chemical or electronic means, but just responsible for the formation of mostly surface  $\text{ReO}_4\text{-II}$  sites on alumina. It has been repeatedly proposed in the literature that the olefin metathesis activity is enhanced by introduction of acidic surface metal oxides ( $\text{WO}_x$ ,<sup>43</sup>  $\text{TaO}_x$ ,<sup>44</sup>  $\text{MoO}_x$ ,<sup>44,46</sup>  $\text{NbO}_x$ ,<sup>45,47</sup> and  $\text{VO}_x$ ,<sup>44,45</sup>), but the current findings demonstrate that surface Brønsted acidity does not affect the intrinsic olefin metathesis reaction and the only function of acidic surface metal oxides is to block the formation of inactive  $\text{ReO}_4\text{-I}$  sites on the most reactive alumina  $\text{Al}_{\text{IV}}$  sites,

which has the effect of increasing the total number of active surface  $\text{ReO}_4\text{-II}$  sites for a given Re loading.

It was estimated that the maximum amount of surface  $\text{ReO}_4\text{-I}$  species on alumina corresponds to 5%  $\text{ReO}_4$ . The lack of propylene metathesis activity for the supported 1–5%  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts suggests that the maximum amount of surface  $\text{ReO}_4\text{-I}$  species corresponds to 5%  $\text{ReO}_4$  (see Figure 10). This is also consistent with the consumption of the basic Al–OH hydroxyls ( $\mu_1\text{-Al}_{\text{IV}}$ ,  $\mu_1\text{-Al}_{\text{VI}}$  and  $\mu_1\text{-Al}_{\text{V}}$  at 3787, 3768, and 3743  $\text{cm}^{-1}$ , respectively) in the IR spectrum for supported 5%  $\text{ReO}_4/\text{Al}_2\text{O}_3$  (see Figure 7) and appearance of a  $\text{ReO}_4\text{-II}$  Raman band above 5% $\text{ReO}_4$  (see Figure 4).

## 4. CONCLUSIONS

Supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts were found to contain two distinct isolated tetra-coordinated dioxo surface  $\text{ReO}_4$  species on alumina (deformed  $\text{ReO}_4\text{-I}$  on basic  $\mu_1\text{-Al}_{\text{IV}}$  sites and  $\text{ReO}_4\text{-II}$  on acidic  $\mu_2\text{-Al}_{\text{VI}}$  and  $\mu_3\text{-Al}_{\text{VI}}$  sites). DFT optimization calculations found that other surface rhenia structures were less or not stable on  $\text{Al}_2\text{O}_3$  (tetra-coordinated mono-oxo, penta-coordinated dioxo, and tetra-coordinated trioxo). The deformed surface  $\text{ReO}_4\text{-I}$  species were not activated by propylene, but the surface  $\text{ReO}_4\text{-II}$  species were readily activated by exposure to propylene. The number of activated surface  $\text{ReO}_4\text{-II}$  species can be markedly increased by adding sacrificial surface  $\text{TaO}_x$  species that block the formation of the low activity deformed surface  $\text{ReO}_4\text{-I}$  species. These new insights allow for fundamental understanding how the (i) oxide support ligand controls the local surface rhenia structure and activation of the surface  $\text{ReO}_4$  species, and (ii) surface metal oxide promoters increase metathesis activity by allowing for the selective formation blocking of inactive surface  $\text{ReO}_4\text{-I}$  species that increases the number of active surface  $\text{ReO}_4\text{-II}$  species. The new molecular level insights are able to resolve many confusing claims about olefin metathesis by supported  $\text{ReO}_4/\text{Al}_2\text{O}_3$  catalysts over the years.

## 5. EXPERIMENTAL SECTION

**5.1. Catalyst Synthesis.** **5.1.1. Supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  Catalysts.** A series of 1–18 wt % supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts were prepared by incipient wetness impregnation of a 65–70 wt % aqueous solution of perrhenic acid,  $\text{HReO}_4$  (Sigma-Aldrich), onto two different  $\text{Al}_2\text{O}_3$  supports (Harshaw batch no. DD351, denoted as "H" and Engelhard batch no. H5433C, denoted as "E") with BET surface areas of 180  $\text{m}^2/\text{g}$  and 170  $\text{m}^2/\text{g}$ , respectively. Using estimations from previous studies and taking consideration of  $\text{ReO}_x$  volatility, the actual Re loadings are approximated to be 1–15.6%.<sup>6</sup> The supported rhenia phase did not volatilize below 6.5%, and the amount of volatilization increased nonlinearly with rhenia loading above this value. The  $\text{Al}_2\text{O}_3$  (Harshaw) support was used for some of the studies because the low fluorescence from this alumina gave rise to higher quality in situ Raman spectra. An incipient wetness point of 1.0 mL  $\text{H}_2\text{O}/\text{g}$  was used for both supports. The alumina supports were impregnated with the aqueous perrhenic acid solution and the powders stirred for 30 min. After impregnation, the samples were initially dried overnight under ambient conditions, further dried at 120 °C for 2 h in flowing air (AirGas, ultrahigh purity (UHP)) and calcined in the flowing air by heating at 1 °C/min and held at 500 °C for 4 h (Thermodyne, furnace model 48000).

**5.1.2. Promoted Supported  $\text{ReO}_x/\text{TaO}_x/\text{Al}_2\text{O}_3$  Catalysts.** The supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts were also promoted with  $\text{TaO}_x$  via incipient wetness impregnation. The supported  $\text{Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$  was prepared from a solution of tantalum ethoxide ( $\text{Ta}(\text{OC}_2\text{H}_5)_5$ , Alfa Aesar, 99.999%) dissolved in toluene (Sigma-Aldrich, 99%) inside a glovebox (Vacuum Atmospheres, Omni-Lab VAC 101965) under a  $\text{N}_2$  environment because of the air sensitivity of the Ta-ethoxide precursor. The supported Ta-ethoxide/ $\text{Al}_2\text{O}_3$  sample was initially dried overnight in the glovebox and subsequently subjected to the same calcination procedure as applied to the supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts. The supported  $\text{Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$  catalyst was impregnated with an aqueous  $\text{HReO}_4$  solution, with the aforementioned preparation and calcination procedures, to synthesize the supported  $\text{ReO}_x/\text{Ta}_2\text{O}_5/\text{Al}_2\text{O}_3$  catalysts. A reverse preparation procedure was also used to make a supported  $\text{Ta}_2\text{O}_5/\text{ReO}_x/\text{Al}_2\text{O}_3$  catalyst in which the rhenia was initially impregnated and calcined prior to the addition of the tantalum oxide.

**5.2. In Situ Diffuse Reflectance Ultraviolet–visible (UV–vis) Spectroscopy.** The UV–vis spectra of the catalysts were collected with a Varian Cary SE UV–vis-NIR spectrophotometer with the Harrick Praying Mantis accessory. Approximately 5–25 mg of each catalyst in finely ground powder form was loaded into an in situ environmental cell (Harrick, HVC-DR2). The catalysts were dehydrated in situ at 500 °C under oxidizing conditions (10%  $\text{O}_2/\text{Ar}$ ) and spectra of the dehydrated samples were collected in the 200–800 nm range at 100 °C, using a scan rate of 15 nm/min and a signal averaging time of 0.6 s. A magnesium oxide sample was used as a standard for obtaining the background absorbance. The spectra of reference compounds,  $\text{KReO}_4$  (Sigma-Aldrich, 99.98%),  $\text{NaReO}_4$  (Sigma-Aldrich, 99.99%),  $\text{NH}_4\text{ReO}_4$  (Sigma-Aldrich, >99%) and  $\text{Re}_2\text{O}_7$  (Alfa Aesar, 99.995%) were collected under ambient conditions. The spectrum of the moisture-sensitive  $\text{Re}_2\text{O}_7$  solid was collected with the sample in its original sealed glass vial. The Kubelka–Munk function  $F(R_\infty)$  was calculated from the absorbance of the UV–vis spectra. The edge energy ( $E_g$ ), or band gap, was determined by finding the intercept of the straight line for the low-energy rise of a plot of  $[F(R_\infty)h\nu]^2$  versus  $h\nu$ , where  $h\nu$  is the incident photon energy. A detailed example of this calculation can be found elsewhere.<sup>48</sup>

**5.3. In Situ XAS (XANES/EXAFS) Spectroscopy.** The in situ  $\text{Re L}_{1\text{-edge}}$  X-ray absorption spectroscopy (XAS) experiments were performed in transmission mode at beamlines X19A and X18B at the National Synchrotron Light Source (NSLS) at the Brookhaven National Laboratory, using ionization chamber detectors for measuring incident and transmitted beam intensities. In addition, a third ionization chamber was used to detect the beam through a reference Re foil for energy calibration and alignment purposes. A plug flow reactor cell with a quartz capillary tube (I.D./O.D. = 0.8/1.0 mm) was used for in situ dehydrated measurements. The supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts were dehydrated at 500 °C using the same dehydration procedure mentioned above and cooled to 70 °C before the spectra were recorded. Reference compounds, trioxo(triphenylsilyloxy) rhenium(VII) (Sigma-Aldrich, 99.9%), iododioxobis (triphenylphosphine) rhenium(V) (Sigma-Aldrich, 99.98%), trichlorooxobis (triphenylphosphine) rhenium(V) (Sigma-Aldrich, 99.99%) and rhenium(VI) oxide,  $\text{ReO}_3$  (Alfa Aesar, 99%) were diluted with Boron Nitride (Sigma-Aldrich, 99%) to give a Re concentration of ~5–10 wt

% and measured under ambient conditions. Data processing and analysis were performed using Athena and Artemis software.

**5.4. In Situ Raman spectroscopy.** **5.4.1. In Situ Raman of Dehydrated Catalysts.** The Raman spectra the supported  $\text{ReO}_x/\text{Al}_2\text{O}_3$  catalysts were obtained with a Horiba-Jobin Yvon LabRam HR instrument equipped with three laser excitations (532, 442, and 325 nm) and a liquid  $\text{N}_2$ -cooled CCD detector (Horiba-Jobin Yvon CCD-3000 V). The 442 nm laser was chosen since it minimized sample fluorescence. Spectral resolution was approximately  $1\text{ cm}^{-1}$  and the wavenumber calibration was checked using the silica standard line at  $520.7\text{ cm}^{-1}$ . The lasers were focused on the samples with a confocal microscope using a 50X objective (Olympus BX-30-LWD). Typically, the spectra were collected at 30 s/scan and 5 scans with a 200  $\mu\text{m}$  hole.

Approximately 5–25 mg of each catalyst in powder form was loaded into an environmental cell (Harrick, HVC-DR2) with a  $\text{SiO}_2$  window and O-ring seals which was kept cool by flowing water. The catalysts were initially dehydrated at a heating rate of 10 °C/min up to 600 °C and held for an hour under a 30 mL/min flow of 10%  $\text{O}_2/\text{Ar}$  (Airgas, certified, 9.989%  $\text{O}_2/\text{Ar}$  balance). Spectra were collected at the lowest possible temperatures as allowed by the fluorescence limitation, typically about 100 or 200 °C.

**5.4.2. In Situ Raman Spectroscopy during  $^{18}\text{O}$ – $^{16}\text{O}$  Isotopic Exchange.** After the aforementioned pretreatment/dehydration procedure, the  $^{18}\text{O}$ – $^{16}\text{O}$  isotope switching of the  $\text{ReO}_x$  was performed at 200 °C with  $\text{H}_2^{18}\text{O}$  (Sigma-Aldrich, Water- $^{18}\text{O}$ , 95 atom %  $^{18}\text{O}$ , CAS no. 14314-42-2). The  $\text{H}_2^{18}\text{O}$  water was manually injected into a flowing gas of 3 mL/min of 10%  $^{16}\text{O}_2/\text{Ar}$  and 27 mL/min of Ar (Airgas, Ar UHP 300) through a T-shaped pipe fitting with an open port using a 5 mL syringe. The minute presence of  $^{16}\text{O}_2$  prevented darkening of the samples, improved the quality of the Raman spectra and was minimally involved in the oxygen isotope exchange. Plastic tubing connected the syringe to the pipe fitting and was connected throughout the experiment to prevent exposure to the ambient atmosphere. The gas lines were wrapped in heating tape and kept at ~150 °C, at the point of injection to the cell inlet, to vaporize the  $\text{H}_2^{18}\text{O}$  water. The injection doses were manually varied depending on the amount of exchanged  $\text{ReO}_x$  observed during the real-time monitoring with online Raman spectroscopy.

**5.5. In Situ Diffuse Reflectance Infrared Fourier Transform Spectroscopy (DRIFTS).** The in situ DRIFT spectra were collected with a Thermo Nicolet 8700 FT-IR spectrometer equipped with a Harrick Praying Mantis attachment (model DRA-2) for diffuse reflectance spectroscopy. Spectra were taken using a MCT detector with a resolution of  $4\text{ cm}^{-1}$  and an accumulation of 72 scans. Approximately 5–25 mg of each catalyst in powder form was loaded into an environmental cell (Harrick, HVC-DR2). The collection of the initial background was performed by first optimizing the beam path and IR absorption signal using the height of the full Harrick sample cup, then removing the Harrick cell and placing a reflective mirror in the laser path. A spectrum was collected using the reflective mirror and was used as the background spectrum throughout the experiment. The catalysts were dehydrated at 500 °C using the same dehydration procedure mentioned above. Spectra were collected at 500, 400, 300, and 200 °C after dehydration to minimize spectral thermal

broadening. Spectra at 200 °C are reported, unless otherwise noted.

**5.6. DFT Calculations.** The periodic DFT calculations have been performed in the framework of the generalized gradient approximation with the PW91 functional,<sup>49</sup> using the Vienna Ab Initio Simulation Package (VASP).<sup>50–52</sup> The one-electron wave functions are developed on a basis set of plane waves. Atomic cores are described with the projector-augmented wave method (PAW)<sup>53</sup> using a cutoff energy of 400 eV.

The previously validated periodic models of the  $\gamma$ -Al<sub>2</sub>O<sub>3</sub> surface<sup>15,16</sup> are based on the nonspinel bulk structure.<sup>54</sup> The most exposed (110) plane, having an area of 74%, and the minority (100) surface, having an area of 16%, were considered for calculations.<sup>15</sup> The (100) and (110) surfaces have been modeled by a four- and six-layer slabs, respectively. The bottom two and three layers are frozen in the geometry of the bulk. Frequency calculations have been carried out by numerical differentiation of the force matrix. All the optimized degrees of freedom were used for the frequency calculations. The surface unit cell dimensions (Å) are  $a = 8.414$ ,  $b = 11.180$  for the (100) plane (unit formula Al<sub>32</sub>O<sub>48</sub>) and  $a = 8.069$ ,  $b = 8.398$  for the (110) plane (unit formula Al<sub>24</sub>O<sub>36</sub>). The  $\Gamma$ -centered 331 Monkhorst–Pack mesh provides a converged energy with respect to Brillouin-zone sampling.<sup>55</sup> All models consider the Re atom in the +7 oxidation state. For the graphic presentation of the structures, Materials Studio 5.5 software is used.<sup>56</sup>

**5.7. Steady-State Propylene Metathesis Reaction.** The catalytic activity measurements were performed in a fixed-bed catalytic reactor under differential conditions (propylene conversion <15%). A separate molecular sieve moisture trap was installed in the inlet propylene gas line to purify the reactants. Both inlet and outlet gas lines were heated using external electric heaters to ~200 °C to prevent condensation of the reactants and products. The catalysts were pretreated in 10% O<sub>2</sub>/Ar at 500 °C for 30 min before cooling down in Ar to the reaction temperature of 70 °C. Then a gas mixture of 1% propylene/1% Ar (internal standard)/He (balance) was introduced to the reactor at the flow rate of ~100 mL/min. The products were analyzed using an online gas chromatograph (Agilent GC 6890) equipped with flame ionization (Agilent serial no.: USC250823H) and thermal conductivity (Restek product no.: PC3533) detectors. Conversion was normalized with propylene flow rate and catalyst weight to obtain reactivity, reported in mmol/g/h. The reported activity values are averages of three measurements, and the error bars indicate the upper and lower confidence levels.

S.L. and I.E.W. acknowledge financial support from U.S. DOE Basic Energy Sciences (Grant No. FG02-93ER14350). Y.L. and A.I.F. acknowledge the U.S. DOE Grant No. DE-FG02-03ER15476 for supporting XAS data analysis. A.I.F. acknowledges the U.S. DOE Grant No. DE-FG02-05ER15688 for supporting the X18B beamline operations. J.H. acknowledges the computing resources from Academic Computer Center CYFRONET AGH (Grant Nos. MNiSW/SGI3700/PK/003/2013, MNiSW/SGI4700/PK/003/2013, MNiSW/IBM\_BC\_HS21/PK/003/2013) and PL-Grid Infrastructure.
